C Library Functions Berl d(3)

delim \$\$

NAME

Berl i, Berl d, Xerl, Aerl - Erlang and inverse Erlang functions

SYNOPSIS

```
#include <erlang.h>
```

double Berl i(int n, double a);

double Berl d(double x, double a);

double Xerl(double b, double a);

double Aerl(double x, double b);

DESCRIPTION

These functions give solutions to the Erlang blocking formula. Erlang formula gives the probability that a communications system with n (or x) lines can't handle any more calls. This also depends on the traffic intensity a. All arguments to these functions must be positive and 0 < b < 1.

Berl i() returns the Erlang loss probability for a integer valued trunk group n and Poisson traffic a

Berl_d() returns the Erlang loss probability for a trunk group x, where x is a real valued variable (double). Second parameter is the Poisson traffic a.

Xerl() returns the number of trunks for a loss probability b and Poisson traffic a.

Aerl() returns the Poisson traffic value for a trunk group x and loss probability b.

ALGORITHM

Berl i() is implemented by using the recursion formula

(1)
$$E(x+1,a) = \{a E(x,a)\} \text{ over } \{x+1+a E(x,a)\}.$$

Berl d() is divided into five sections depending on the value of the parameters.

Range 1: x < a and a > 0.01

Apply the continued fraction expansion formula.

Range 2: x >= a and x > 60

Determine a value x' such that a > x' (i.e. apply an integral valued shift of x). Call Berl_d again with x' < a and use the recurrence relation to arrive at the original value of x.

Range 3: x >= a and 1 <= x <= 60

Apply Rapp's parabola followed by the recurrence relation (1).

Range 4: x >= a and a > 0.01 and x < 1

Apply Laguerre quadrature, Abramowitz [2], p. 923

Range 5: 0 < x < 1 and 0 < a <= 0.01

Apply formula (48) from Farmer and Kaufman [ref 1], p. 161

In **Xerl**() we first determine with inequality

$$E(n,a) > E(n+1,a)$$

the position of the interval [N,N+1] such that $N \le X \le N+1$. By using the secant iteration method, we determine the exact root of the function

$$f(x) = Berl d(x,a) - b.$$

Evaluation time of **Xerl()** is proportional to the result value.

Aerl(): First we compute a starting value for a. Then a is improved using the Newton's iteration scheme. The iteration process is stopped as soon as the relative error in E(x,a) is smaller than some prescribed value. When b is very small, this function has long evaluation time.
